

## STREPTOCOCCAL C5a PEPTIDASE VACCINE

This application is a continuation-in-part of U.S. Application Serial No. 08/589,756 filed January 22, 1996. USSN 08/589,756 is incorporated by reference herein.

### Background of the Invention

5           There are several different  $\beta$ -hemolytic streptococcal species that have been identified. *Streptococcus pyogenes*, also called group A streptococci, is a common bacterial pathogen of humans. Primarily a disease of children, it causes a variety of infections including pharyngitis, impetigo and sepsis in humans. Subsequent to infection, autoimmune complications such as rheumatic fever and  
10 acute glomerulonephritis can occur in humans. This pathogen also causes severe acute diseases such as scarlet fever, necrotizing fasciitis and toxic shock.

Sore throat caused by group A streptococci, commonly called "strep throat," accounts for at least 16% of all office calls in a general medical practice, depending on the season. Hope-Simpson, E., "Streptococcus pyogenes in the  
15 throat: A study in a small population, 1962-1975," J. Hyg. Camb., 87:109-129 (1981). This species is also the cause of the recent resurgence in North America and four other continents of toxic shock associated with necrotizing fasciitis. Stevens, D. L., "Invasive group A streptococcus infections," Clin. Infect. Dis., 14:2-13 (1992). Also implicated in causing strep throat and occasionally in  
20 causing toxic shock are groups C and G streptococci. Hope-Simpson, E., "Streptococcus pyogenes in the throat: A study in a small population, 1962-1975," J. Hyg. Camb., 87:109-129 (1981).

Group B streptococci, also known as *Streptococcus agalactiae*, are responsible for neonatal sepsis and meningitis. T.R. Martin et al., "The effect of  
25 type-specific polysaccharide capsule on the clearance of group B streptococci from the lung of infant and adult rats", J. Infect Dis., 165:306-314 (1992). Although frequently a member of vaginal mucosal flora of adult females, from 0.1 to 0.5/1000 newborns develop serious disease following infection during delivery. In spite of the high mortality from group B streptococcal infections,  
30 mechanisms of the pathogenicity are poorly understood. Martin, T. R., et al.,

"The effect of type-specific polysaccharide capsule on the clearance of Group B streptococci from the lung of infant and adult rats," J. Infect. Dis., 165:306-314 (1992).

Streptococcal infections are currently treated by antibiotic therapy.

- 5 However, 25-30% of those treated have recurrent disease and/or shed the organism in mucosal secretions. At present no means is available to prevent streptococcal infections. Historically, streptococcal vaccine development has focused on the bacterium's cell surface M protein. Bessen, D., et al., "Influence of intranasal immunization with synthetic peptides corresponding to conserved epitopes of M protein on mucosal colonization by group A streptococci," Infect. Immun., 56:2666-2672 (1988); Bronze, M. S., et al., "Protective immunity evoked by locally administered group A streptococcal vaccines in mice," Journal of Immunology, 141:2767-2770 (1988).
- 10

- Two major problems will limit the use, marketing, and possibly FDA approval, of an M protein vaccine. First, more than 80 different M serotypes of *S. pyogenes* exist and new serotypes continually arise. Fischetti, V. A., "Streptococcal M protein: molecular design and biological behavior," Clin. Microbiol. Rev., 2:285-314 (1989). Thus, inoculation with one serotype-specific M protein will not likely be effective in protecting against other M serotypes.
- 15
- 20 The second problem relates to the safety of an M protein vaccine. Several regions of the M protein contain antigenic epitopes which are immunologically cross-reactive with human tissue, particularly heart tissue. The N-termini of M proteins are highly variable in sequence and antigenic specificity. Inclusion of more than 80 different peptides, representing this variable sequence, in a vaccine
- 25 would be required to achieve broad protection against group A streptococcal infection. New variant M proteins would still continue to arise, requiring ongoing surveillance of streptococcal disease and changes in the vaccine composition. In contrast, the carboxyl-termini of M proteins are conserved in sequence. This region of the M protein, however, contains an amino acid
- 30 sequence which is immunologically cross-reactive with human heart tissue. This property of M protein is thought to account for heart valve damage associated with rheumatic fever. P. Fenderson et al., "Tropomyosinsharies immunologic

epitopes with group A streptococcal M proteins, J. Immunol. 142:2475-2481 (1989). In an early trial, children who were vaccinated with M protein in 1979 had a ten fold higher incidence of rheumatic fever and associated heart valve damage. Massell, B. F., et al., "Rheumatic fever following streptococcal vaccination, JAMA, 207:1115-1119 (1969).

Other proteins under consideration for vaccine development are the erythrogenic toxins, streptococcal pyrogenic exotoxin A and streptococcal pyrogenic exotoxin B. Lee, P. K., et al., "Quantification and toxicity of group A streptococcal pyrogenic exotoxins in an animal model of toxic shock syndrome-like illness," J. Clin. Microb., 27:1890-1892 (1989). Immunity to these proteins could prevent the deadly symptoms of toxic shock, but may not prevent colonization by streptococci.

Thus, there remains a continuing need for an effective means to prevent or ameliorate streptococcal infections. More specifically, a need exists to develop compositions useful in vaccines to prevent or ameliorate colonization of host tissues by streptococci, thereby reducing the incidence of strep throat and impetigo. Elimination of sequelae such as rheumatic fever, acute glomerulonephritis, sepsis, toxic shock and necrotizing fasciitis would be a direct consequence of reducing the incidence of acute infection and carriage of the organism. A need also exists to develop compositions useful in vaccines to prevent or ameliorate infections caused by all  $\beta$ -hemolytic streptococcal species, namely groups A, B, C and G.

### Summary of the Invention

The present invention provides a vaccine, and methods of vaccination, effective to immunize a susceptible mammal against  $\beta$ -hemolytic *Streptococcus*. The susceptible mammal could be a human or a domestic animal such as a dog, a cow, a pig or a horse. Such immunization could prevent, ameliorate or reduce the incidence of  $\beta$ -hemolytic *Streptococcus* colonization in the mammal. The vaccine contains an immunogenic amount of streptococcal C5a peptidase (SCP), wherein the SCP is a variant of wild-type SCP in combination with a physiologically-acceptable, non-toxic vehicle.

- A “variant” of SCP is a polypeptide or oligopeptide SCP that is not completely identical to native SCP. Such a variant SCP can be obtained by altering the amino acid sequence by insertion, deletion or substitution of one or more amino acid. The amino acid sequence of the protein is modified, for example by substitution, to create a polypeptide having substantially the same or improved qualities as compared to the native polypeptide. The substitution may be a conserved substitution. A “conserved substitution” is a substitution of an amino acid with another amino acid having a similar side chain. A conserved substitution would be a substitution with an amino acid that makes the smallest change possible in the charge of the amino acid or size of the side chain of the amino acid (alternatively, in the size, charge or kind of chemical group within the side chain) such that the overall peptide retains its spacial conformation but has altered biological activity. For example, common conserved changes might be Asp to Glu, Asn or Gln; His to Lys, Arg or Phe; Asn to Gln, Asp or Glu and Ser to Cys, Thr or Gly. Alanine is commonly used to substitute for other amino acids. The 20 essential amino acids can be grouped as follows: alanine, valine, leucine, isoleucine, proline, phenylalanine, tryptophan and methionine having nonpolar side chains; glycine, serine, threonine, cystine, tyrosine, asparagine and glutamine having uncharged polar side chains; aspartate and glutamate having acidic side chains; and lysine, arginine, and histidine having basic side chains. L. Stryer, Biochemistry (2d ed.) p. 14-15; Lehninger, Biochemistry, p. 73-75.

- The amino acid changes are achieved by changing the codons of the corresponding nucleic acid sequence. It is known that such polypeptides can be obtained based on substituting certain amino acids for other amino acids in the polypeptide structure in order to modify or improve antigenic or immunogenic activity. For example, through substitution of alternative amino acids, small conformational changes may be conferred upon a polypeptide which result in increased activity or enhanced immune response. Alternatively, amino acid substitutions in certain polypeptides may be used to provide residues which may then be linked to other molecules to provide peptide-molecule conjugates which retain sufficient antigenic properties of the starting polypeptide to be useful for other purposes.

One can use the hydropathic index of amino acids in conferring interactive biological function on a polypeptide, wherein it is found that certain amino acids may be substituted for other amino acids having similar hydropathic indices and still retain a similar biological activity. Alternatively, substitution of like amino acids may be made on the basis of hydrophilicity, particularly where the biological function desired in the polypeptide to be generated is intended for use in immunological embodiments. The greatest local average hydrophilicity of a "protein", as governed by the hydrophilicity of its adjacent amino acids, correlates with its immunogenicity. U.S. Patent 4,554,101. Accordingly, it is noted that substitutions can be made based on the hydrophilicity assigned to each amino acid.

In using either the hydrophilicity index or hydropathic index, which assigns values to each amino acid, it is preferred to conduct substitutions of amino acids where these values are  $\pm 2$ , with  $\pm 1$  being particularly preferred, and those with in  $\pm 0.5$  being the most preferred substitutions.

The variant SCP comprises at least seven amino acid residues, preferably about 100 to about 1500 residues, and more preferably about 300 to about 1200 residues, and even more preferably about 500 to about 1180 residues, wherein the variant SCP has at least 50%, preferably at least about 80%, and more preferably at least about 90% but less than 100%, contiguous amino acid sequence homology or identity to the amino acid sequence of a corresponding native SCP.

The amino acid sequence of the variant SCP polypeptide corresponds essentially to the native SCP amino acid sequence. As used herein "correspond essentially to" refers to a polypeptide sequence that will elicit a protective immunological response substantially the same as the response generated by native SCP. Such a response may be at least 60% of the level generated by native SCP, and may even be at least 80% of the level generated by native SCP. An immunological response to a composition or vaccine is the development in the host of a cellular and/or antibody-mediated immune response to the polypeptide or vaccine of interest. Usually, such a response consists of the subject producing antibodies, B cell, helper T cells, suppressor T cells, and/or

cytotoxic T cells directed specifically to an antigen or antigens included in the composition or vaccine of interest.

The SCP may be a variant of SCP from group A *Streptococcus* (SCPA), group B *Streptococcus* (SCPB), group C *Streptococcus* (SCPC) or group G

5 *Streptococcus* (SCPG).

A variant of the invention may include amino acid residues not present in the corresponding native SCP or deletions relative to the corresponding native SCP. A variant may also be a truncated "fragment" as compared to the corresponding native SCP, i.e., only a portion of a full-length protein. For  
10 example, the variant SCP may vary from native SCP in that it does not contain a cell wall insert. SCP variants also include peptides having at least one D-amino acid.

The variant SCP of the vaccine may be expressed from an isolated DNA sequence encoding the variant SCP. For example, the variant SCP may vary  
15 from native SCP in that it does not contain a signal sequence or a cell wall insert. The DNA may encode the specificity crevice or the catalytic domain. In particular the DNA may encode amino acid residue 130, 193, 295 or 512 of the catalytic domain, or amino acid residues 260, 261, 262, 415, 416 or 417 of the specificity crevice, or encode modifications at such residues. In particular, the  
20 DNA may encode SCPA49D130A, SCPA49H193A, SCPA49N295A, SCPA49S512A, SCPA1D130A, SCPA1H193A, SCPA1N295A, SCPA1S512A, SCPBD130A, SCPBH193A, SCPBN295A, SCPBS512A or ΔSCPA49. For the above listing SCPA49H193A means an SCP from group A Streptococci serotype 49, wherein the His at residue number 193 is replaced with Ala. The SCP of the  
25 vaccine may lack enzymatic C5ase or peptidase activity. The vaccine may also contain an immunological adjuvant. The vaccine can be used to prevent infection by group A *Streptococcus*, group B *Streptococcus*, group C *Streptococcus* or group G *Streptococcus*. The vaccine may comprise an immunogenic recombinant streptococcal C5a peptidase conjugated or linked to  
30 an immunogenic peptide or to an immunogenic polysaccharide. "Recombinant" is defined as a peptide or nucleic acid produced by the processes of genetic

engineering. The terms “protein,” “peptide” and “polypeptide” are used interchangeably herein.

The streptococcal C5a peptidase vaccine can be administered by subcutaneous or intramuscular injection. Alternatively, the vaccine can be administered by oral ingestion or intranasal inoculation.

The present invention further provides isolated and purified SCP peptides, wherein the SCP is a variant of wild-type SCP and isolated and purified polynucleotides encoding a variant SCP. For example, the SCP may include amino acid residue 130, 193, 295 or 512 of the catalytic domain, or amino acid residues 260, 261, 262, 415, 416 or 417 of the specificity crevice. The SCP may be SCPA49D130A, SCPA49H193A, SCPA49N295A, SCPA49S512A, SCPA1D130A, SCPA1H193A, SCPA1N295A, SCPA1S512A, SCPBD130A, SCPBH193A, SCPBN295A, SCPBS512A or ΔSCPA49.

### **Brief Description of the Drawings**

Figure 1. Architecture of C5a peptidase from β-hemolytic streptococci. D indicates an aspartic acid residue; H indicates histidine; S indicates serine; L indicates leucine; P indicates proline; T indicates threonine; and N indicates asparagine. R<sub>1</sub>, R<sub>2</sub>, R<sub>3</sub> and R<sub>4</sub> indicate repeated sequences. The numbers indicate the amino acid residue position in the peptidase.

Figure 2. Alignment of the amino acid sequence of SCP from group A streptococci serotype 49 (SEQ ID NO:1), group A streptococci serotype 12 (SEQ ID NO:2), group B streptococci (SEQ ID NO:3) and group A streptococci serotype 1 (SEQ ID NO:23). The sequences are identical except for the indicated amino acid positions. The triangle (▽) indicates the predicted cleavage point of the signal peptidase. Amino acids predicted to be in the enzyme's active site are marked by asterisks. Deletions in the amino acid sequence are indicated by dots and are boxed. The asterisks (\*) indicate the amino acid residues of the catalytic domain.

Figure 3. Construction of SCP insertion and deletion mutants. Black box indicates deleted region.

Figure 4. Single color FACS analysis. Fluorescence data were analyzed by gating on PMNs. A second gate was set to count high staining cells defined by the first gate. Air sacs were inoculated with  $1 \times 10^6$  CFU.

Figure 5. Persistence of Wild-type and SCPA<sup>-</sup> serotype M49 streptococci following intranasal infection.

Figure 6. Comparison of the ability of SCPA<sup>-</sup> mutants of serotype M6 Group A streptococcus to colonize mice following intranasal infection. Compares BALB/c mice (ten in each experimental group) inoculated with  $2 \times 10^7$  CFU of M6 streptococci. Throat swabs were cultured each day on blood agar plates containing streptomycin. Mice were considered positive if plates contained one  $\beta$ -hemolytic colony. Data were analyzed statistically by the  $\chi^2$  test.

Figure 7. Construction of  $\Delta$ SCPA49 vaccine and immunization protocol.

Figure 8. Rabbit antibody neutralizes SCPA activity associated with different serotypes. Bar 1 is a positive control and contained rhC5a which was not preincubated before exposure to PMNs. Bar 10 is a control which lacks rhC5a. Whole, intact bacteria, preincubated with normal rabbit serum (bar 2, M1 90-131; bar 4, M6 UAB200; bar 6, M12 CS24; bar 8, M49 CS101) or preincubated with rabbit anti-SCPA49 serum (bar 3, M1 90-131; bar 5, M6 UAB200; bar 7, M12 CS24; bar 9, M49 CS101), were incubated with  $20 \mu\text{l}$  of  $5 \mu\text{M}$  rhC5a for 45 minutes. Residual rhC5a was assayed by its capacity to activate PMNs to adhere to BSA-coated microtiter plate wells. Adherent PMNs were stained with crystal violet.

Figure 9. Serum IgG and secretory IgA responses after intranasal immunization of mice with the purified  $\Delta$ SCPA49 protein. Serum and saliva levels of SCPA49 specific IgG were determined by indirect ELISA. Sera from each mouse were diluted to 1: 2,560 in PBS; saliva was diluted 1:2 in PBS. Figure 9A shows the sIgA experimental results; Figure 9B shows the IgG experimental results.

Figure 10. Comparison of the ability of serotype M49 streptococci to colonize immunized and non-immunized CD1 female mice. Each experimental group contained 13 mice which were infected intranasally (i.n.) with  $2.0 \times 10^8$

CFU. The data were analyzed statistically by the  $\chi^2$  test. Figures 10A and 10B show the results of the repeated experiment.

Figure 11. Competitive ELISA Comparison of wild-type and variant SCP binding to polyclonal antibody. Plate antigen is recombinant wild-type SCPA49 (100 ng/well). Competing antigen is indicated by the legend.

Figure 12. Competitive ELISA Comparison of SCPA1, SCPA49 and SCPB binding to polyclonal antibody. Plate antigen is recombinant wild-type SCPA49 (100 ng/well). Competing antigen is indicated by the legend. SCPA1 and SCPA49 used in the experiments depicted in this Figure comprised Asn<sup>32</sup> through His<sup>1139</sup>. SCPB used in the experiments depicted in this Figure was made according to Chmouryguina, I. et al., "Conservation of the C5a Peptidase Gene in Group A and B Streptococci", *Infect. Immun.*, 64:2387-2390 (1996).

#### **Detailed Description of the Invention**

An important first line of defense against infection by many bacterial pathogens is the accumulation of phagocytic polymorphonuclear leukocytes (PMNs) and mononuclear cells at the site of infection. Attraction of these cells is mediated by chemotactic stimuli, such as host factors or factors secreted by the invading organism. The C5a chemoattractant is pivotal to the stimulation of this inflammatory response in mammals. C5a is a 74 residue glycopeptide cleaved from the fifth component (C5) of complement. Phagocytic cells respond in a directed manner to a gradient of C5a and accumulate at the site of infection. C5a may be the most immediate attractant of phagocytes during inflammation. As PMNs infiltrate an inflammatory lesion they secrete other chemokines, such as IL8, which further intensify the inflammatory response.

Streptococcal C5a peptidase (SCP) is a proteolytic enzyme located on the surface of pathogenic streptococci where it destroys C5a, as C5a is locally produced. SCP specifically cleaves the C5a chemotaxin at the PMN binding site (between His<sup>67</sup>-Lys<sup>68</sup> residues of C5a) and removes the seven most C-terminal residues of C5a. This cleavage of the PMN binding site eliminates the chemotactic signal. Cleary, P., et al., "Streptococcal C5a peptidase is a highly specific endopeptidase," *Infect. Immun.*, 60:5219-5223 (1992); Wexler, D. E., et

al., "Mechanism of action of the group A streptococcal C5a inactivator," Proc. Natl. Acad. Sci. USA, 82:8144-8148 (1985).

- SCP from group A streptococci is a subtilisin-like serine protease with an  $M_r$  of 124,814 da and with a cell wall anchor motif which is common to many
- 5 Gram positive bacterial surface proteins. The architecture of C5a peptidase is given in Figure 1. The complete nucleotide sequence of the streptococcal C5a peptidase gene of *Streptococcus pyogenes* has been published. Chen, C., and Cleary, P., "Complete nucleotide sequence of the streptococcal C5a peptidase gene of *Streptococcus pyogenes*," J. Biol. Chem., 265:3161-3167 (1990). In
  - 10 contrast to Subtilisins, SCP has a very narrow substrate specificity. This narrow specificity is surprising in light of the marked similarities between their catalytic domains. Cleary, P., et al., "Streptococcal C5a peptidase is a highly specific endopeptidase," Infect. Immun., 60:5219-5223 (1992). Residues involved in charge transfer are conserved, as are residues on both sides of the binding
  - 15 pocket. However, the remaining amino acid sequence of SCP is unrelated to that of Subtilisins. More than 40 serotypes of Group A streptococci were found to produce SCP protein or to harbor the gene. Cleary, P., et al., "A streptococcal inactivator of chemotaxis: a new virulence factor specific to group A streptococci," in Recent Advances in Streptococci and Streptococcal Disease
  - 20 p.179-180 (S. Kotami and Y. Shiokawa ed.; Reedbooks Ltd., Berkshire, England; 1984); Podbielski, A., et al., "The group A streptococcal virR49 gene controls expression of four structural vir regulon genes," Infect. Immun., 63:9-20 (1995).

- The catalytic domain or active site of SCP is composed of the charge
- 25 transfer system and the specificity crevice. The charge transfer system, also called the catalytic domain, contains residues Asp<sup>130</sup>, His<sup>193</sup>, Asn<sup>295</sup> and Ser<sup>512</sup> (Figs. 1 and 2). A modification, i.e., a deletion, insertion or substitution, of any one of these amino acids will inactivate the enzyme. The specificity crevice, on the other hand, is predicted to be formed by Ser<sup>260</sup>, Phe<sup>261</sup>, Gly<sup>262</sup>, Ile<sup>415</sup>, Tyr<sup>416</sup>
  - 30 and Asp<sup>417</sup>. Modification by substitution of these amino acids could change the substrate specificity of the enzyme or eliminate proteolytic activity altogether. Modification by deletion of these amino acids would also inactivate the enzyme.

The catalytic domain depends on the tertiary structure of the protein that is created when the mature enzyme folds into its active state. This domain is not formed from a contiguous linear array of amino acid residues. Alternatively, modification may also reduce binding of variant SCP to the substrate. Binding may be reduced by 50%, 70% or even 80%.

- A C5a peptidase enzyme associated with group B streptococci has also been identified. Hill, H. R., et al., "Group B streptococci inhibit the chemotactic activity of the fifth component of complement," J. Immunol. 141:3551-3556 (1988). Restriction mapping and completion of the *scpB* nucleotide sequence showed that *scpB* is 97-98% similar to *scpA*. See Figure 2 for comparison of the amino acid sequence of SCP from group A streptococci serotype 49, group A streptococci serotype 12, group B streptococci and group A streptococci serotype 1 (SEQ ID NO:1, SEQ ID NO:2, SEQ ID NO:3 and SEQ ID NO:23, respectively). More than 30 strains, representing all serotypes of group B streptococci carry the *scpB* gene. Cleary P.P., et al. "Similarity between the Group B and A streptococcal C5a Peptidase genes," Infect. Immun. 60:4239-4244 (1992); Suvorov A.N., et al., "C5a peptidase gene from group B streptococci," in Genetics and Molecular Biology of Streptococci, Lactococci, and Enterococci p. 230-232 (G. Dunny, P. Cleary and L. McKay (ed.); American Society for Microbiology, Washington, D.C.; 1991).

- Human isolates of groups G and C streptococci also harbor *scpA*-like genes. Some group G strains were shown to express C5a specific protease activity on their surface. Cleary, P. P., et al., "Virulent human strains of group G streptococci express a C5a peptidase enzyme similar to that produced by group A streptococci," Infect. Immun. 59:2305-2310 (1991). Therefore, all serotypes (>80) of group A streptococci, group B streptococci, group C streptococci and group G streptococci produce the SCP enzyme.

- SCP assists streptococci to colonize a potential infection site, such as the nasopharyngeal mucosa, by inhibiting the influx of phagocytic white cells to the site of infection. This impedes the initial clearance of the streptococci by the host. The impact of SCP on inflammation, C5a leukocyte chemotaxis and streptococcal virulence was examined using streptococcal strains with well-

defined mutations in the protease structural gene. SCP variants were constructed by targeted plasmid insertion and by replacement of the wild-type gene with *scpA* containing a specific internal deletion. Variants lacked C5a protease activity and did not inhibit the chemotactic response of human or mouse PMNs to C5a in vitro.

A mouse connective tissue air sac model was used to confirm that SCP retards the influx of phagocytic cells and clearance of streptococci from the site of infection. A connective tissue air sac is generated by injecting a small amount of air and PBS (with or without streptococci in it) with a 25-gauge needle under the skin on the back of a mouse. Boyle, M.D.P. et al., "Measurement of leukocyte chemotaxis in vivo," Meth. Enzymol., 162:101:115 (1988). At the end of the experiment, the mice were euthanized by cervical dislocation, the air sacs dissected from the animals, and the air sacs homogenized in buffer. An advantage of the air sac model is that the air sac remains inflated for several days and free of inflammation, unless an irritant is injected. Thus, injected bacteria and the resulting inflammatory response remains localized over short periods of infection.

The air sac model was modified to compare clearance of wild-type SCP<sup>+</sup> and SCP<sup>-</sup> streptococci (i.e., group A streptococci which carried a variant non-functional form of SCP), and to analyze the cellular infiltrate at an early stage of infection. Tissue suspensions were assayed for viable streptococci on blood agar plates and the cellular infiltrate was analyzed by fluorescent cell sorting (FACS). In FACS analysis, individual cells in suspension are labelled with specific fluorescent monoantibodies. Aliquots of labelled cells are injected into a FAC-Scan flowcytometer, or fluorescent cell sorter, which counts cells based on their unique fluorescence. The experiments using the air sac model indicated that streptococci that were SCP<sup>+</sup> were more virulent than streptococci that were SCP<sup>-</sup>.

A study was performed to measure production of human antibody, both IgG and IgA, against SCP in human sera and saliva. O'Connor, SP, et al., "The Human Antibody Response to Streptococcal C5a Peptidase," J. Infect. Dis. 163:109-16 (1991). Generally, sera and saliva from young, uninfected children lacked antibody to SCP. In contrast, most sera and saliva specimens from

healthy adults had measurable levels of anti-SCP IgG and SCP-specific secretory IgA (anti-SCP sIgA). Paired acute and convalescent sera from patients with streptococcal pharyngitis possessed significantly higher levels of anti-SCP IgG than did sera from healthy individuals. Sera containing high concentrations of anti-SCP immunoglobulin were capable of neutralizing SCP activity. Detection of this antibody in >90% of the saliva specimens obtained from children who had recently experienced streptococcal pharyngitis demonstrated that children can produce an antibody response.

Even though the human subjects produced IgG and IgA against SCP in response to a natural streptococcal infection, it was not known whether the anti-SCP immunoglobulin provides any protection against infection. Further, it was not known if the SCP protein could act as a vaccine against  $\beta$ -hemolytic streptococcal colonization or infection. First, a study was performed to examine the role of SCP in colonization of the nasopharynx. Following intranasal infection with live group A streptococci, throat cultures were taken daily for up to ten days. Wild-type and isogenic SCP-deficient mutant streptococci were compared for the ability to persist in the throat over this ten day period. As predicted, the SCP-deficient mutant streptococci were cleared from the nasopharynx more rapidly.

The same intranasal mouse model was used to test the capacity of SCP to induce immunity that will prevent colonization. A variant form of the recombinant *scpA49* gene beginning at the nucleotide that encodes Thr<sup>63</sup> was cloned. This variant is referred to as  $\Delta$ SCPA49, and is 2908 bp in length (see Example 4 below). Variant SCP protein was purified from an *E. coli* recombinant by affinity chromatography. Sera from rabbits vaccinated intradermally with this protein preparation neutralized SCP activity in vitro. Purified protein (40  $\mu$ g) was administered intranasally to mice over a period of five weeks. Immunized mice cleared streptococci in 1-2 days; whereas, throat cultures of non-immunized mice remained positive for up to 10 days. The experiment was repeated on three sets of mice, vaccinated with three separate preparations of a SCP protein.

Further experiments were performed to determine whether immunization of an animal with a single antigen would prevent colonization by several serotypes.  $\Delta$ SCPA49 was cloned into an expression vector and expressed in *E. coli*. The affinity purified variant  $\Delta$ SCPA49 protein proved to be highly

- 5 immunogenic in mice and rabbits. Although the purified variant  $\Delta$ SCPA49 immunogen lacked enzymatic activity, it induced high titers of rabbit antibodies that were able to neutralize peptidase activity associated with M1, M6, M12 and M49 streptococci *in vitro*. This confirmed that anti-peptidase antibodies lack serotype specificity. Four sets of mice were then intranasally immunized with
- 10 the purified variant  $\Delta$ SCPA49 and each was challenged with a different serotype of group A streptococcus. The immunization of mice with  $\Delta$ SCPA49 protein stimulated significant levels of specific salivary sIgA and serum IgG antibodies and reduced the potential of wild-type M1, M2, M6, M11 and M49 streptococci to colonize. These experiments confirm that immunization with streptococcal
- 15 C5a peptidase vaccine is effective in preventing the colonization of the nasopharynx.

Experiments were also performed to develop variant SCPs from an M1 OF strain and from the M49 OF<sup>+</sup> strain. Since active SCP could be harmful to the host, it was important that the variant proteins lacked enzymatic activity.

- 20 Amino acids that are required for catalytic activity were replaced with those expected to inactivate the enzyme.

Two properties of the variant proteins were evaluated. First, the specific activities of the wild-type and variant proteins were determined by PMN adherence assay. These experiments indicated that the substituted amino acids

- 25 reduced enzymatic activity by greater than 90%. Second, the variant proteins were also compared to the wild-type protein for their capacity to bind antibody directed against the wild-type enzyme. Competitive ELISA assays were used for this purpose. The results indicated that the amino acid substitutions did not alter the ability of antibody to bind to the variant proteins.

- 30 All earlier protection studies had been performed by administering affinity purified  $\Delta$ SCPA49 protein intranasally without adjuvant. Intramuscular or subcutaneous (SQ) injection of antigens, however, is historically a preferred,

more accepted method of vaccine delivery. Therefore, experiments were performed to test whether SQ injections of  $\Delta$ SCPA with monophosphoryl lipid A (MPL) and alum ( $\text{AlPO}_4$ ) induced a protective immune response and whether that response reduced colonization when the challenge strain of group A

- 5 streptococcus differed in serotype from the source of the SCPA vaccine. The capacity of immunized mice to clear streptococci from the oral-nasal pharyngeal mucosa was evaluated by throat culture or by sampling dissected nasal tissue.

- The number of streptococci associated with nasal tissue decreased with time, as expected, and the decrease was more rapid and complete in mice
- 10 immunized with SCPA antigen. The results confirmed that a single SCPA antigen can induce protection against heterologous serotypes. Protection is afforded by antibody that neutralizes peptidase activity on the bacterial surface. This increases the influx of phagocytes within a few hours from the time streptococci are deposited on mucosal tissue. Rapid clearance of streptococci by
- 15 phagocytes is presumed to prevent subsequent multiplication and persistence of the bacteria. Thus, SQ injection of SCPA antigen with adjuvant consistently induced a vigorous antibody response.

- The present invention thus provides a vaccine for use to protect mammals against  $\beta$ -hemolytic *Streptococcus* colonization or infection. In one embodiment
- 20 of this invention, as is customary for vaccines, the variant streptococcal C5a peptidase can be delivered to a mammal in a pharmacologically acceptable vehicle. Vaccines of the present invention can also include effective amounts of immunological adjuvants, known to enhance an immune response.

- The SCP can be conjugated or linked to another peptide or to a
- 25 polysaccharide. For example, immunogenic proteins well-known in the art, also known as "carriers," may be employed. Useful immunogenic proteins include keyhole limpet hemocyanin (KLH), bovine serum albumin (BSA), ovalbumin, human serum albumin, human gamma globulin, chicken immunoglobulin G and bovine gamma globulin. Useful immunogenic polysaccharides include group A
- 30 *Streptococcal* polysaccharide, C-polysaccharide from group B *Streptococci*, or the capsular polysaccharides of *Streptococcus pneumoniae* or group B

*Streptococci*. Alternatively, polysaccharides or proteins of other pathogens that are used as vaccines can be conjugated to, linked to, or mixed with SCP.

- Further provided are isolated and purified nucleic acid molecules, e.g., DNA molecules, comprising a preselected nucleic acid segment which encodes
- 5 at least a portion of a Streptococcal C5a peptidase, i.e., they encode SCP or a variant thereof as described herein, e.g., SCPA49S512A, SCPA49D130A, SCPA49N295A, SCPA1S512A, SCPA1D130A, SCPA1N295A,  $\Delta$ SCPA49, SCPBS512A, SCPBD130A, SCPBH193A or SCPBN295A, or any combination of these mutations. For example, the invention provides an expression cassette
  - 10 comprising a preselected DNA segment which codes for an RNA molecule which is substantially identical (sense) to all or a portion of a messenger RNA ("target" mRNA), i.e., an endogenous or "native" SCP mRNA. The preselected DNA segment in the expression cassette is operably linked to a promoter. As used herein, "substantially identical" in sequence means that two nucleic acid
  - 15 sequences have at least about 65%, preferably about 70%, more preferably about 90%, and even more preferably about 98%, contiguous nucleotide sequence identity to each other. Preferably, the preselected DNA segment hybridizes under hybridization conditions, preferably under stringent hybridization conditions, to a nucleic acid molecule encoding the corresponding native SCP.
  - 20 As used herein, "substantially pure" means an object species is the predominant species present (i.e., on a molar basis it is more abundant than any other individual species in the composition), and preferably a substantially purified fraction is a composition wherein the object species comprises at least about 50 percent (on a molar basis) of all macromolecular species present.
  - 25 Generally, a substantially pure composition will comprise more than about 80 percent of all macromolecular species present in the composition, more preferably more than about 85%, about 90%, about 95%, and about 99%. Most preferably, the object species is purified to essential homogeneity (contaminant species cannot be detected in the composition by conventional detection
  - 30 methods) wherein the composition consists essentially of a single macromolecular species.

- As used herein, the term "recombinant nucleic acid" or "preselected nucleic acid," e.g., "recombinant DNA sequence or segment" or "preselected DNA sequence or segment" refers to a nucleic acid, e.g., to DNA, that has been derived or isolated from any appropriate source, that may be subsequently
- 5 chemically altered *in vitro*, so that its sequence is not naturally occurring, or corresponds to naturally occurring sequences that are not positioned as they would be positioned in a genome which has not been transformed with exogenous DNA. An example of preselected DNA "derived" from a source, would be a DNA sequence that is identified as a useful fragment within a given
- 10 organism, and which is then chemically synthesized in essentially pure form. An example of such DNA "isolated" from a source would be a useful DNA sequence that is excised or removed from said source by chemical means, e.g., by the use of restriction endonucleases, so that it can be further manipulated, e.g., amplified, for use in the invention, by the methodology of genetic engineering.
- 15 Recovery or isolation of a given fragment of DNA from a restriction digest can employ separation of the digest on polyacrylamide or agarose gel by electrophoresis, identification of the fragment of interest by comparison of its mobility versus that of marker DNA fragments of known molecular weight, removal of the gel section containing the desired fragment, and separation of the
- 20 gel from DNA. See Lawn et al., Nucleic Acids Res., **9**, 6103 (1981), and Goeddel et al., Nucleic Acids Res., **8**, 4057 (1980). Therefore, "preselected DNA" includes completely synthetic DNA sequences, semi-synthetic DNA sequences, DNA sequences isolated from biological sources, and DNA sequences derived from RNA, as well as mixtures thereof.
- 25 As used herein, the term "derived" with respect to a RNA molecule means that the RNA molecule has complementary sequence identity to a particular DNA molecule.

- Nucleic acid molecules encoding amino acid sequence variants of a SCP are prepared by a variety of methods known in the art. These methods include,
- 30 but are not limited to, isolation from a natural source (in the case of naturally occurring amino acid sequence variants) or preparation by oligonucleotide-

mediated (or site-directed) mutagenesis, PCR mutagenesis, and cassette mutagenesis of an earlier prepared variant or a non-variant version of the SCP.

To immunize a subject, the variant SCP, is administered parenterally, usually by intramuscular or subcutaneous injection in an appropriate vehicle.

- 5 Other modes of administration, however, such as oral delivery or intranasal delivery, are also acceptable. Vaccine formulations will contain an effective amount of the active ingredient in a vehicle. The effective amount is sufficient to prevent, ameliorate or reduce the incidence of  $\beta$ -hemolytic *Streptococcus* colonization in the target mammal. The effective amount is readily determined
- 10 by one skilled in the art. The active ingredient may typically range from about 1% to about 95% (w/w) of the composition, or even higher or lower if appropriate. The quantity to be administered depends upon factors such as the age, weight and physical condition of the animal or the human subject considered for vaccination. The quantity also depends upon the capacity of the
- 15 animal's immune system to synthesize antibodies, and the degree of protection desired. Effective dosages can be readily established by one of ordinary skill in the art through routine trials establishing dose response curves. The subject is immunized by administration of the SCP in one or more doses. Multiple doses may be administered as is required to maintain a state of immunity to
- 20 streptococci.

- Intranasal formulations may include vehicles that neither cause irritation to the nasal mucosa nor significantly disturb ciliary function. Diluents such as water, aqueous saline or other known substances can be employed with the subject invention. The nasal formulations may also contain preservatives such
- 25 as, but not limited to, chlorobutanol and benzalkonium chloride. A surfactant may be present to enhance absorption of the subject proteins by the nasal mucosa.

- Oral liquid preparations may be in the form of, for example, aqueous or oily suspension, solutions, emulsions, syrups or elixirs, or may be presented dry
- 30 in tablet form or a product for reconstitution with water or other suitable vehicle before use. Such liquid preparations may contain conventional additives such as

suspending agents, emulsifying agents, non-aqueous vehicles (which may include edible oils), or preservative.

To prepare a vaccine, the purified SCP can be isolated, lyophilized and stabilized. The SCP peptide may then be adjusted to an appropriate

- 5 concentration, optionally combined with a suitable vaccine adjuvant, and packaged for use. Suitable adjuvants include but are not limited to surfactants, e.g., hexadecylamine, octadecylamine, lysolecithin, dimethyldioctadecylammonium bromide, N,N-dioctadecyl-N'-N-bis(2-hydroxyethyl-propane di-amine), methoxyhexadecyl-glycerol, and pluronic
- 10 polyols; polyanions, e.g., pyran, dextran sulfate, poly IC, polyacrylic acid, carbopol; peptides, e.g., muramyl dipeptide, MPL, aimethylglycine, tuftsin, oil emulsions, alum, and mixtures thereof. Other potential adjuvants include the B peptide subunits of *E. coli* heat labile toxin or of the cholera toxin. McGhee, J.R., et al., "On vaccine development," Sem. Hematol., 30:3-15 (1993). Finally,
- 15 the immunogenic product may be incorporated into liposomes for use in a vaccine formulation, or may be conjugated to proteins such as keyhole limpet hemocyanin (KLH) or human serum albumin (HSA) or other polymers.

- The application of SCP for vaccination of a mammal against colonization offers advantages over other vaccine candidates. Prevention of colonization or
- 20 infection by inoculation with a single protein will not only reduce the incidence of the very common problems of strep throat and impetigo, but will also eliminate sequelae such as rheumatic fever, acute glomerulonephritis, sepsis, toxic shock and necrotizing fasciitis.

- The following examples are intended to illustrate but not limit the
- 25 invention.

### EXAMPLE 1

#### Construction and *In Vitro* Analysis of Insertion and Deletion Mutants in *scpA49* and *scpA6*

- a) **Bacterial strains and culture conditions.** *S. pyogenes* strain CS101
- 30 is a serotype M49, and serum opacity positive (OF<sup>+</sup>) strain. CS159 is a clinical isolate with a deletion which extends through the M gene cluster and *scpA*. A spontaneous, streptomycin resistant derivative of strain CS101, named

CS101Sm, was selected by plating streptococci from a stationary phase culture on tryptose blood agar containing streptomycin (200 µg/ml). Streptococcal strains CS210 and CS463 are spontaneous streptomycin resistant derivatives of OF<sup>+</sup>, class II, serotype M2, and M11 strains, respectively. Streptococcal strains 90-131 and UAB200 are spontaneous streptomycin resistant derivatives of OF<sup>-</sup>, class I, serotype M1 and M6 human isolates of group A streptococci, respectively.

CS101::pG<sup>+</sup>host5 is strain CS101 with pG<sup>+</sup>host5 integrated into the chromosome at an unknown location, but outside *scpA* and the *emm* gene cluster.

- 10 *Escherichia coli* strain ER1821 (from New England Biolabs, Inc. Beverly, MA) was used as the recipient for the suicide vector, plasmid pG<sup>+</sup>host5. Plasmid pG<sup>+</sup>host5 was obtained from Appligene, Inc. Pleasanton, CA. Streptococci were grown in Todd-Hewitt broth supplemented with 2% neopeptone or 1% yeast extract, or on tryptose agar plates with 5% sheep blood. *E. coli* strain ER1821
- 15 containing plasmid pG<sup>+</sup>host5 was grown in LB broth with erythromycin (300 µg/ml). Streptococci with plasmid pG<sup>+</sup>host5 were cultured in Todd-Hewitt broth with 1% yeast extract (THY) containing 1 µg/ml of erythromycin (Erm).

- SCP refers to streptococcal C5a peptidase from β-hemolytic *Streptococcus* generally. SCPA1, SCPA12, SCPA49, SCPA6 are the specific
- 20 peptidases from group A *Streptococcus* M serotype 1, 12, 49 and 6 strains, respectively. The term *scpA* refers to the gene encoding SCP from group A streptococci. *ScpA1*, *scpA12*, *scpA6* and *scpA49* are the genes encoding the SCPA1, SCPA12, SCPA49 and SCPA6 peptidases. SCPB and *scpB* refer to the peptidase and gene from group B streptococci. The amino acid sequences for
  - 25 SCPA49 (SEQ ID NO:1), SCPA12 (SEQ ID NO:2), SCPA1 (SEQ ID NO:23 and SCPB (SEQ ID NO:3) are given in Figure 2.

- b) Construction of *scpA49* insertion mutant.** Well-defined insertion mutants of *scpA49* were constructed using plasmid insertion and gene replacement methods. An internal *scpA49* *Bgl*III - *Bam*HI fragment, the insertion
- 30 target, was ligated into the thermosensitive shuttle vector pG<sup>+</sup>host5 to form plasmid pG<sup>+</sup>:*scpA1.2* and transformed into *E. coli* ER1821 (Figure 3). The pG<sup>+</sup>host5 vector contains an *E. coli* origin of replication that is active at 39°C, a

temperature sensitive Gram positive origin of replication (active at 30°C and inactive at 39°C in streptococci), and an erythromycin resistance gene for selection. High temperature forces the plasmid to integrate into the chromosomal DNA of group A streptococci by homologous recombination at frequencies ranging from  $10^{-2}$  to  $10^{-3}$ .

Recombinant plasmid DNA pG::scpA1.2 was electroporated into CS101 recipient cells. Transformants were selected on THY-agar plates containing 1 µg/ml erythromycin at 30°C. Chromosomal integrants which resulted from recombination between the plasmid insert and the chromosomal *scpA49* were selected by erythromycin resistance at 39°C. Two insertion mutants, M14 and M16, were analyzed. EmrS revertants of strain M14 and M16 were obtained by passage in THY without antibiotic at 30°C and finally plated at 37°C without Erm selection. Colonies that had lost the plasmid were isolated to confirm that the mutant phenotype resulted from insertion of the plasmid into *scpA49*, rather than from a simultaneous unrelated mutation.

**c) Construction of the *scpA6* insertion mutants.** The *scpA6* insertion mutant AK1.4 was constructed as described in section (b) above. Recombinant plasmid DNA, pG::scpA1.2, contains an internal *Bgl*II-*Hind*III fragment of *scpA* gene. This plasmid was electroporated into UAB200 recipient cells and transformants were selected on THY agar plates containing erythromycin at 30°C. A chromosomal integrant of pG::scpA1.2, strain AK1.4, which resulted from recombination between the plasmid insert and the chromosomal *scpA6* was selected by growth on agar medium containing erythromycin at 39°C. Insertion into *scpA6* was confirmed by Southern blotting using *scpA* as the probe, and PCR using an M13 universal primer (5'-GTAAAACGACGGCCAGT-3') (SEQ ID NO:6), specific for the plasmid, and an *scpA* For835 primer (5'-AAGGACGACACATTGCGTA-3') (SEQ ID NO:7), specific for the chromosomal *scpA* of GAS.

**d) Introduction of a defined deletion into *scpA* (Figure 3).** A mutant strain with a defined deletion internal to *scpA49* was constructed to eliminate the possibility that insertions in *scpA49* could be polar and reduce expression of downstream genes, unknown genes which could also contribute to the

organism's virulence. First, a defined deletion in *BgIII-HindIII* fragment of *scpA* was produced by inside-out PCR with primer 1 (5'-  
 GGGGGGGAATTCGTAGCGGGTATCATGGGAC-3'), SEQ ID NO:4, and  
 primer 2 (5'-GGGGGGGAATTCGGGTGCTGCAATATCTGGC-3'), SEQ ID  
 NO:5. Underlined nucleotides correspond to *scpA* sequences with coordinates  
 2398 and 2322, respectively, and the bold faced nucleotides correspond to a  
*EcoRI* recognition site. The primers were selected to produce an in-frame  
 deletion in the *scpA* gene. These primers copy plasmid DNA in opposite  
 directions and define the boundaries of the deletion. Innis, M.A., et al., eds.,  
 10 PCR Protocols A Guide to Methods and Applications (Academic Press, 1990).  
 Plasmid pG::scpA1.2 DNA was used as template.

The amplified product was digested with *EcoRI* and ligated to plasmid  
 pG<sup>+</sup>host5. The resulting plasmid pG:: $\Delta$ *scpA*1.1 contained an 76 bp deletion  
 internal to *scpA*. This in-frame deletion removed 25 amino acids, including the  
 15 serine which forms part of the predicted catalytic center of serine proteases.  
 Chen, C., and Cleary, P., "Complete nucleotide sequence of the streptococcal  
 C5a peptidase gene of *Streptococcus pyogenes*," J. Biol. Chem., 265:3161-3167  
 (1990). An *EcoRV* site was created at the point of deletion. DNA which  
 overlaps the deletion was sequenced to confirm the boundaries of the deletion.

20 The plasmid pG:: $\Delta$ *scpA*1.1, which contains the deletion, was transformed  
 into *E. coli* ER1821. Colonies were selected for *ErmR* and then screened for the  
 appropriate *scpA* deletion using miniprep plasmid DNA restricted by *EcoRI*.  
 The precise boundaries of the deletion were confirmed by DNA sequencing.  
 Plasmid pG:: $\Delta$ *scpA*1.1 was electroporated into strain CS101Sm as described  
 25 above, then integrants were selected by grown on *Erm* at 39°C. Integration of  
 the plasmid into the chromosome of the M49 strain CS101sm using high  
 temperature selection. The insertion location was confirmed by PCR. Growth  
 of CS101Sm (pG:: $\Delta$ *scpA*1.1) at low temperature without erythromycin selection  
 resulted in high frequency segregation of *ErmS* revertants which have lost the  
 30 plasmid by random deletion event or by excision due to recombination between  
 the duplicated *scpA* sequences created by the insertion. Two deletion mutants  
 were identified, MJ2-5 and MJ3-15, and were studied further. The chromosomal

deletion left behind by recombinational excision of plasmid pG:: $\Delta scpA1.1$  was defined by PCR and Southern hybridization to EcoRV digested DNA.

- e) **In vitro effects of mutations on SCP.** The impact of insertions and deletions on the expression of SCP antigen and peptidase activity was assessed by Western blot and PMNs adherence assays. Streptococci were incubated in 100 ml THY at 37°C overnight. The culture pellet was washed two times in 5 ml cold 0.2 M NaAcetate (pH 5.2), then suspended in 1 ml TE-sucrose buffer (20% sucrose 10 mM Tris, 1 mM EDTA, pH 7.0) and 40  $\mu$ l Mutanolysin. The mixture was rotated at 37°C for 2 hr, then centrifuged 5 min at 4500 rpm.
- Supernatants contained protease inhibitor, 100 mM phenylmethyl sulfonyl fluoride (PMSF). Electrophoresis and Western blotting methods were performed as described in Laemmli, U. K., "Cleavage of structural proteins during the assembly of the head of bacteriophage T4," Nature 227:680-685 (1970). The primary antiserum used to detect SCP protein on Western and colony blots was prepared by immunization of a rabbit with purified recombinant SCP protein. Binding was detected by anti-rabbit antibody alkaline phosphatase conjugate.

- C5a peptidase activity was measured using a PMN adherence assay. Booth, S. A. et al., "Dapsone suppresses integrin-mediated neutrophil adherence function," J. Invest. Dermatol. 98:135-140 (1992). After incubation of C5a (Sigma, St. Louis, MO) with streptococcal extracts or purified protease, residual C5a can activate PMNs to become adherent to BSA coated wells. First, microtiter wells were coated with 0.5% BSA in PBS and incubated for 1 hr at 37°C. Human PMNs were isolated by centrifugation in Ficoll Hypaque (Sigma, St. Louis, MO). 40  $\mu$ l of intact streptococci or protein extracts were incubated with 20  $\mu$ l of 5  $\mu$ M C5a in 340  $\mu$ l of PBS with 1% glucose and 0.1%  $\text{CaCl}_2$  at 37°C for 45 min. BSA-coated wells were washed with PBS, and resuspended PMNs and residual C5a were added to wells. The mixture was incubated for 45 min at 37°C in 7%  $\text{CO}_2$ . Finally, wells were washed to remove nonadherent PMNs. Adherent PMNs were stained with crystal violet and the  $\text{OD}_{570\text{nm}}$  was read in an ELISA reader. The optical density is proportional to the amount of residual C5a or inversely proportional to the amount of SCP activity.

Mutanolysin extracts of cell surface proteins from parent and mutant cultures were analyzed by Western blot using SCPA specific serum. Mutants were confirmed to lack SCPA. Extracts of SCPA<sup>-</sup> mutants AK1.4 and MJ3-15 did not react with anti-SCPA serum. SCPA proteins of the expected size were  
5 observed in extracts from the wild-type strains CS101 and UAB200. Failure of mutant strains AK1.4 and MJ3-15 to produce C5a peptidase activity was verified by comparing their capacity to destroy rhC5a. Exposure of isolated PMNs to rhC5a induced them to become adherent to BSA coated microtiter wells. Incubation with streptococci or purified SCPA specifically cleaved rhC5a and  
10 altered its potential to activate PMNs. PMNs that responded to residual rhC5a and bound to BSA coated wells, were stained, then measured spectrophotometrically. Incubation of rhC5a with parent cultures UAB200 and CS101 destroyed rhC5a, which inhibited PMN adherence by 58.8% and 54.5%, respectively. In contrast SCPA<sup>-</sup> mutants, AK1.4 and MJ3-15, did not alter rhC5a  
15 or adherence of PMNs to BSA coated wells (Table 1). This experiment confirmed the Western blots and demonstrated that SCPA<sup>-</sup> cultures lack other proteases which might degrade rhC5a.

Table 1. Phagocytosis assay and PMN adherence assay of wild-type and mutant strains

Strain	Description	Colony forming units (cfu)/ml		Fold increase in cfu/ml	Percent inhibition of C5a induced PMN adherence*
		Time=0h	Time=3h		
5	UAB200 M6 <sup>+</sup> , SCPA <sup>+</sup>	1.8 x 10 <sup>3</sup>	7.2 x 10 <sup>4</sup>	40	58.8
	AK1.4 M6 <sup>+</sup> , SCPA <sup>-</sup>	1.2 x 10 <sup>3</sup>	4.5 x 10 <sup>4</sup>	37.5	0
10	CS101 M49 <sup>+</sup> , SCPA <sup>+</sup>	1.0 x 10 <sup>4</sup>	4.9 x 10 <sup>5</sup>	49	54.5
	MJ3-15 M49 <sup>+</sup> , SCPA <sup>-</sup>	1.5 x 10 <sup>4</sup>	2.1 x 10 <sup>5</sup>	14	0

\*Percent inhibition = [(OD<sub>570nm</sub> of PMNs activated by C5a alone - OD<sub>570nm</sub> PMNs activated by C5a preincubated with bacteria / OD<sub>570nm</sub> of PMNs activated by C5a alone)] x 100%.

- 15 Although M protein expression was not expected to be influenced by mutations in *scpA*, assays were performed to assess whether SCPA<sup>-</sup> mutant streptococci still expressed M protein and had the ability to resist phagocytosis. Growth of streptococci in fresh human blood during 3 hours incubation is indicative of antiphagocytic M protein on their surface. R.C. Lancefield,
- 20 "Differentiation of Group A Streptococci with a Common R Antigen into Three Serological Types, with Special Reference to Bactericidal Test," *J. Exp. Med.*, **106**, pp. 525-685 (1957). As expected, parent streptococci UAB200 and CS101 increased 40 and 49 fold, respectively (Table 1). The M<sup>+</sup> SCPA<sup>-</sup> cultures, strains AK1.4 and MJ3-15, increased 37.5 and 14-fold, respectively, confirming that
- 25 *scpA* mutations had little effect on M protein expression or resistance to phagocytosis in whole human blood. The somewhat poorer growth of both mutant strains in rotated blood was reproducible and unexpected. The growth rates of mutant and parent cultures in human plasma were indistinguishable. It is possible that inactivation of SCPA allowed C5a to accumulate in rotated blood
- 30 which in turn activated PMNs. Activated PMNs are more phagocytic and better able to kill M<sup>+</sup> streptococci. Surface protein extracts contain M6 and M49

antigen when analyzed by Western blot using anti-M49 and anti-M6 antisera, confirming that mutations in SCPA did not alter M protein expression.

## EXAMPLE 2

### 5 SCP Delays Recruitment of Phagocytes and Clearance of Streptococci from Subdermal Sites of Infection

In order to verify that SCP was responsible for the inactivation of C5a, the insertion and deletion mutants of *scpA49* were constructed as described in Example 1 above, and tested for activity. When insertions or deletions were  
10 introduced into *scpA49*, the variant SCP was not able to destroy C5a-activated adherence of PMNs to microtiter plates.

The impact of mutations in *scpA49* on virulence was tested using an animal model where streptococci remained localized, and where the influx of inflammatory cells could be analyzed. To test the hypothesis that SCP functions  
15 very early to retard initial clearance of the organism, the fate of SCP<sup>+</sup> and SCP<sup>-</sup> streptococci just 4 hours after inoculation of connective tissue air sacs was compared. Moreover, the dissemination of streptococci to lymph nodes and spleens after this short period of infection was also assessed.

CD1 male outbred mice (25 g) obtained from Charles River Breeding  
20 Laboratory, Wilmington, MA were used for all experiments. A connective tissue air sac was generated by injecting 0.9 ml of air and 0.1 ml group A streptococci diluted in PBS with a 25-gauge needle under the skin on the back of the mouse. In some experiments the SCP<sup>+</sup> CS101::pG<sup>+</sup>host5 was used as a positive control. In other experiments strain CS101Sm was used as the positive  
25 control. Mice were euthanized by cervical dislocation 4 hours after infection. Where indicated, all four inguinal lymph nodes, spleen and air sac were dissected from the animals and homogenized in PBS. Tissue suspensions were assayed for viable colony forming unit (CFU) on blood agar plates containing 1 µg/ml erythromycin or 200 µg/ml streptomycin.

30 In a preliminary experiment air sacs were fixed on slides, stained with Wright's stain and examined microscopically. Although counts of granulocytes by this method were unreliable, there appeared to be significantly fewer residual

SCP<sup>-</sup> than wild-type streptococci in fixed tissue. Additional experiments were performed in an attempt to measure this difference. Dispersed cell populations of air sacs were prepared by grinding the air sac in PBS and passing them through Nylon monofilament mesh (TETKO Co. New York).

- 5       The cells were pelleted by centrifugation 5 min at 300 × g and resuspended at 5 × 10<sup>6</sup>/ml in FACS buffer (Hank's balanced salt solution without phenol red, 0.1% NaN<sub>3</sub>, 1.0% BSA fraction V). Cells (1.0 × 10<sup>6</sup>) were stained directly with 1 μg FITC anti-mouse Mac-1 or indirectly with 1 μg Biotin conjugated anti-mouse Gr-1 followed by 1 μg Streptavidin labelled with
- 10   fluorescence or FITC. Monoclonal antibodies, Mac-1 and Gr-1, were obtained from Pharmingen, Inc. CA. Labeled cells were fixed in 1.0% paraformaldehyde. Fluorescence profiles were generated using a FAC-Scan flowcytometer and Consort 32 software (Becton Dickinson). Mouse PMNs were purified from whole blood by Ficoll Hypaque density gradient centrifugation and used as a
- 15   standard to defined PMNs in mixed populations. For measurement of specifically labeled cells, the mean fluorescence for each antibody marker was determined and gates were set to reflect intensely labeled cells. Controls included unstained cells, and cells exposed to only streptavidin FITC.

- 20       Two experiments were performed. The first compared the *scpA49* insertion mutant M16 to its SCP<sup>+</sup> parent culture, strain CS101. The second compared the *scpA49* deletion mutant MJ3-15, to its parent, strain CS101Sm. (Table 2) In both experiments homogenized air sacs from mice inoculated with SCP<sup>-</sup> streptococci contained fewer numbers of streptococci after 4 hours than air sacs inoculated with wild-type streptococci. The first experiment showed a two-
- 25   fold reduction and the second showed a four-fold reduction. These differences were statistically significant at P<0.05 and P<0.001, respectively, using an Unpaired t-test. It was also observed that wild-type SCP<sup>+</sup> streptococci were found in spleen homogenates from 7 of 8 mice and 6 of 8 mice; whereas, the SCP<sup>-</sup> mutants were rarely found in the spleen. The opposite was true for lymph
- 30   node homogenates. Nodes from 10 of 16 mice infected with SCP<sup>-</sup> streptococci harbored viable streptococci; whereas, only 4 of 16 nodes from mice infected

with wild-type streptococci contained viable bacteria. This difference was determined to be statistically significant at  $P < 0.05$  using the Fisher's exact test.

**Table 2: Distribution of SCP<sup>+</sup> and SCP<sup>-</sup> streptococci  
4 hours after air sac infection**

Strains	No. of Mice <sup>a</sup>	No. of positive cultures		Homogenized Air Sac <sup>c</sup>
		spleen <sup>b</sup>	lymph node	
CS101pG (SCP <sup>+</sup> )	8	7	2	$1.3 \times 10^8 \pm 2.2 \times 10^7$
M16 (SCP <sup>-</sup> )	8	0	5	$6.0 \times 10^7 \pm 1.3 \times 10^7$
CS101Sm (SCP <sup>+</sup> )	8	6	2	$1.6 \times 10^8 \pm 2.6 \times 10^7$
MJ3-15 (SCP <sup>-</sup> )	8	1	5	$3.7 \times 10^7 \pm 1.5 \times 10^7$

<sup>a</sup> Each mouse was inoculated with  $3 \times 10^8$  CFU of stationary phase streptococci.

<sup>b</sup> Difference in the frequency of isolation of SCP<sup>+</sup> streptococci from spleens relative to SCP<sup>-</sup> streptococci was statistically significant ( $P < 0.05$ ) for each experiment by the Fisher's exact test.

<sup>c</sup> Differences in CFU isolated from homogenized air sacs (means  $\pm$  SEMs) were significant, strains CS101pG (SCP<sup>+</sup>) and M16 (SCP<sup>-</sup>) and MJ3-15 (SCP<sup>-</sup>) ( $P < 0.001$ ) for each experiment by unpaired *t* test.

The more rapid clearance of streptococci from air sacs resulted from more intense recruitment of PMNs. The total cell population, the percentage of Mac-1 positive granulocytes (Springer, G. et al., "Mac-1:macrophage differentiation antigen identified by monoclonal antibody," Eur. J. Immunol. 9:301-306 (1979)), and the percentage of Gr-1 positive PMN (Brummer, E. et al., "Immunological activation of polymorphonuclear neutrophils for fungal killing: studies with murine cells and blastomyces dermatitidis in vitro," J. Leuko. Bio. 36:505-520 (1984)) in air sacs were compared by single color FACS analysis. Clark, J. M., "A new method for quantitation of cell-mediated immunity in the mouse," J. Reticuloendothel. Soc. 25:255-267 (1979). Briefly, in a FACS analysis, individual cells in suspension are labelled with specific fluorescent monoantibodies. Aliquots of labelled cells are injected into a FAC-

Scan flowcytometer or fluorescent cell sorter which counts cells based on their unique fluorescence.

Air sacs infected with the SCP<sup>-</sup> deletion mutant contained twice as many inflammatory cells as those inoculated with SCP<sup>+</sup> streptococci (Figure 4). A

- 5 hundred-fold increase in the inoculum size did not alter this difference. Air sacs infected with  $1 \times 10^6$  SCP<sup>-</sup> cells, strain MJ3-15, contained three times more Gr-1 positive cells than those inoculated with the SCP<sup>+</sup> culture. In air sacs inoculated with SCP<sup>+</sup> streptococci approximately 6% of the cells were PMNs and 21% were other kinds of Mac-1<sup>+</sup> granulocytes, including PMNs. In contrast, air sacs
- 10 inoculated with SCP<sup>-</sup> streptococci contained predominately PMNs. Gr-1 positive cells were equal to or greater than the number of Mac-1 positive cells. Flow cytometer gates were set to measure only high staining granulocytes. The remaining 70-80% of cells not stained with either antibody were likely either low staining granulocytes, red blood cells or lymphocytes. Large numbers of
- 15 lymphocytes were observed microscopically in Wrights stained air sac preparations.

- SCP<sup>+</sup> colonies of streptococci that emerged from spleen homogenates were highly encapsulated, resembling water drops. In contrast the few SCP<sup>-</sup> colonies arising from lymph nodes, were more like the inoculum. They were
- 20 mixtures of non-mucoid and moderately mucoid colonies. These data suggest that M<sup>+</sup>SCP<sup>+</sup> encapsulated streptococci can adapt, multiply and invade the bloodstream within 4 hours after infection. The basis for differential trafficking of mutant and wild-type streptococci may be due to the more vigorous influx of phagocytic cells in response to SCP<sup>-</sup> bacteria. Macrophages and/or skin
  - 25 dendritic cells may more rapidly engulfed SCP streptococci and delivered them to lymph nodes. Reduction of mutant streptococci relative to wild-type is an unexpected finding, because SCP<sup>-</sup> streptococci are M<sup>+</sup> and resistant to phagocytosis by human neutrophils in vitro.

### EXAMPLE 3

- 30 **SCP Is Required for Colonization of the Mouse Nasopharynx**

Mice were inoculated intranasally to evaluate the relative capacity of wild-type (SCP<sup>+</sup>) and SCP<sup>-</sup> streptococci to colonize the nasopharynx.

Streptomycin resistant M49 strain CS101 and deletion mutant MJ3-15 were used in these experiments. Cultures were not mouse passed in order to avoid selection of variants that might be uniquely mouse virulent, but no longer depend on M protein and/or SCP for persistence in the animal.

- 5 Sixteen hour cultures of challenge streptococcal strains ( $1 \times 10^8$  -  $9 \times 10^8$  CFU), grown in Todd-Hewitt broth containing 20% normal rabbit serum and resuspended in 10 $\mu$ l of PBS, were administered intranasally to 25g female CD1 (Charles River Breeding Laboratories, Inc., Wilmington, MA.) or BALB/c mice (Sasco, Omaha NE). Viable counts were determined by plating dilutions of
- 10 cultures on blood agar plates. Throat swabs were taken daily from anesthetized mice for 6 to 10 days after inoculation and streaked onto blood agar plates containing 200ug/ml streptomycin. After overnight incubation at 37°C, the number of  $\beta$ -hemolytic colonies on plates were counted. All challenge strains were marked by streptomycin resistance to distinguish them from  $\beta$ -hemolytic
- 15 bacteria which may be persist in the normal flora. Throat swabs were cultured on blood agar containing streptomycin. The presence of one  $\beta$ -hemolytic colony was taken as a positive culture.

- CD1 outbred mice were intranasally inoculated with  $2 \times 10^8$  stationary phase CFU. The nasopharynxes of anesthetized mice were swabbed daily for 8-
- 20 10 days and streaked on blood agar containing streptomycin. Differences between SCP<sup>+</sup> and SCP<sup>-</sup> were evident by day 1, however, statistically significant differences were not observed until days 3 and 4 (Figure 5). By day four 9/18 mice infected with M<sup>+</sup>SCP<sup>+</sup> streptococci produced positive throat cultures, whereas only 2/18 mice infected with M<sup>+</sup>SCP<sup>-</sup> strain retained streptococci in
- 25 their throats. Four of 18 mice died from infection with SCP<sup>+</sup> streptococci. None of the mice following infection with SCP<sup>-</sup> bacteria succumbed to the infection. The numbers of colonies on the blood agar plates were also consistent with more rapid clearance of SCP<sup>-</sup> streptococci. For example, on the third day cultures from seven mice contained >100 SCP<sup>+</sup> CFU, whereas, only one mouse
- 30 inoculated SCP<sup>-</sup> streptococci contained > 100 CFU.

Because M49 streptococci are more often associated with skin infections the above experiments were repeated with an M6 strain, a serotype more often

associated with throat infections. An insertion mutant, strain AK1.4, was constructed using the M6 strain UAB200 and the strategy previously described in Example 1. Strain AK1.4 was also cleared more rapidly than the wild-type M6 culture from the nasopharynx. (Figure 6) The above experiments confirm that group A streptococci are dependent upon SCP for persistence in the mouse nasopharynx. All SCP<sup>-</sup> variants used in the above experiments were M<sup>+</sup>, i.e. they resisted phagocytosis by fresh human blood. Yet, they were cleared from the nasopharyngeal mucosa.

#### EXAMPLE 4

##### 10      **Intranasal Immunization of Mice with Purified Recombinant SCPA49 Blocks Colonization Following Intranasal Challenge**

a) Construction of recombinant vaccine  $\Delta$ SCPA49 encoding Thr<sup>63</sup> through His<sup>1031</sup> (Figures 2 and 7).

A PCR fragment which corresponds to a truncated form of the *scpA49* gene was cloned from CS101 M49 group A streptococci ( $\Delta$ SCPA49). This fragment was amplified by PCR using a forward primer beginning at nucleotide 1033 and a reverse primer beginning at nucleotide 3941 (numbering corresponding to that of Chen, C., and Cleary, P., "Complete nucleotide sequence of the streptococcal C5a peptidase gene of *Streptococcus pyogenes*," J. Biol. Chem., 265:3161-3167 (1990)). The fragment was ligated to the thrombin binding site of glutathione transferase gene on the pGex-4T-1 high expression vector from Pharmacia Inc. The plasmid containing the recombinant *scpA* fragment, designated pJC6, has been deposited in the American Type Culture Collection, Rockville, MD, under the provision of the Budapest Treaty, and assigned ATCC accession number 98225.

The  $\Delta$ SCPA49, a 2908 bp fragment of *scpA49*, was amplified by PCR using an *scpA49* forward primer containing a *Bam*HI recognition sequence (5'-CCCCCGGATCCACCAAAACCCACAACTC-3') (SEQ ID NO:8) and an *scpA* reverse primer (5'-GAGTGGCCCTCCAATAGC-3') (SEQ ID NO:9). Sequences which code for the signal peptide and membrane anchor regions of the SCPA protein were deleted from the resulting PCR product. PCR products were digested with *Bam*HI and ligated to *Bam*HI and *Sma*I restriction sites in the

thrombin recognition site of the glutathione S-transferase gene on the pGEX-4T-1 high expression vector from Pharmacia Inc. (Piscataway, NJ). The recombinant plasmid was transformed into *E.coli* DH5 $\alpha$ . The  $\Delta$ SCPA49 fusion protein from one transformant, *E.coli* (pJC6), was purified by affinity

- 5 chromatography on a glutathione Sepharose 4B column. The transferase-SCP fusion protein from one *E. coli* clone was expressed and purified by affinity chromatography on a glutathione Sepharose 4b column. All methods are described by the manufacturer (Pharmacia). The  $\Delta$ SCPA49 was cleaved from the hybrid protein by thrombin digestion. The thrombin was removed from
- 10 eluted SCP by chromatography on a benzamidine Sepharose 6B column (Pharmacia). Following digestion with thrombin, thrombin was removed by chromatography on a benzamidine-Sepharose 6B column. Methods of expression and purification are described by the manufacturer. The affinity purified protein was confirmed to be pure  $\Delta$ SCPA49 by SDS-PAGE and by
- 15 Western blot. This affinity purified, truncated  $\Delta$ SCPA49 protein lacked peptidase activity when tested by the PMN adherence assay (described in Example 1 above). Hyperimmune antiserum, directed against purified  $\Delta$ SCPA49 was prepared in rabbits.

- b) Immunization and challenge protocol.** Four week old, outbred,
- 20 CD1 female mice were immunized by administration of 20 $\mu$ g of affinity purified  $\Delta$ SCPA49 in 10 $\mu$ l PBS into each nostril. Mice were immunized 3 times on alternating days and boosted again three weeks after the third immunization. After two weeks rest, mice were again boosted. D. Bessen et al., "Influence of Intranasal Immunization with Synthetic Peptides Corresponding to Conserved
- 25 Epitopes of M Protein on Mucosal Colonization by Group A Streptococci," Infect. Immun., **56**, pp. 2666-2672 (1988). Control mice received only PBS. Prior to infection, all mice which were immunized with  $\Delta$ SCPA49 protein were determined by ELISA to have high titers of antibodies against  $\Delta$ SCPA49 antigen in their serum and saliva. Group A streptococci, strain CS101 ( $2.0 \times 10^8$  CFU),
- 30 CS210 ( $3.6 \times 10^8$  CFU), CS463 ( $7.8 \times 10^8$  CFU), 90-131 ( $3.4 \times 10^8$  CFU), and UAB200 ( $9.6 \times 10^8$  CFU) were used to intranasally challenge the mice 7 days

after the last vaccine booster. Animal studies were performed according to National Institutes of Health guidelines.

- c) **Sample collection and ELISA.** Blood and saliva samples were collected from anesthetized mice after immunization. All sera were tested for the presence of SCPA49 antibodies by ELISA, as previously described. S.P. O'Connor et al., "The Human Antibody Response to Streptococcal C5a Peptidase," *J. Infect. Dis.*, **163**, pp. 109-116 (1990). Purified SCPA49 protein was bound to microtiter wells by addition of 500ng of purified protein in 0.05M bicarbonate buffer (pH 9.6). After overnight incubation at 4°C the wells were washed, then blocked with 0.5% BSA in PBS for 1 hour. Salivation was stimulated in mice by injection of 100 µl of a 0.1% pilocarpine (Sigma) solution subcutaneously. Saliva samples were collected and spun at 14,000 rpm for 5 min in an Eppendorf microcentrifuge. The supernatants were tested for the presence of secretory IgA against ΔSCPA49 protein by ELISA. ELISA titers represent the highest dilution of individual serum and saliva which had an OD<sub>405</sub> ≥ 0.1.

**d) Evaluation of Antibody Response to ΔSCPA49**

- The immunogenicity of the subunit ΔSCPA49 vaccine was evaluated. Rabbits were immunized with purified ΔSCPA49. The rabbits developed high levels of antibodies against ΔSCPA49 protein as determined by ELISA. Although the purified ΔSCPA49 immunogen lacked functional activity, hyperimmune rabbit antiserum could neutralize the peptidase activity of purified wild-type SCPA49 enzyme *in vitro*. Moreover, undiluted rabbit antiserum against ΔSCPA49 protein was able to neutralize C5a peptidase activity associated with different serotypes (Figure 8). C5a peptidase activity associated with intact M1, M6 and M12 streptococci was inhibited by this antiserum, confirming that antibody against ΔSCPA49 protein lacks serotype specificity.

- Also, serum and saliva samples were obtained from ten immunized and ten control mice to assess the immunogenicity of ΔSCPA49 protein when administered via the intranasal route without adjuvants. Mice which were immunized with purified ΔSCPA49 protein developed high titers of ΔSCPA49-specific IgG in their sera, compared to control mice immunized with PBS

(Figure 9). Titers of serum IgG directed against  $\Delta$ SCPA49 ranged from 1:10,240 to 1:20,480. In contrast,  $\Delta$ SCPA49-specific IgG titer of control mice was not detectable in sera. Mice immunized with purified  $\Delta$ SCPA49 protein also showed a significant increase in  $\Delta$ SCPA49-specific salivary sIgA relative to control mice. Specific sIgA titers in saliva of immunized mice were greater than 1:16. In contrast, sIgA directed against  $\Delta$ SCPA49 in the saliva of control mice was not detectable. The relative concentration of IgG and sIgA in serum diluted 1/2560 and saliva diluted 1/2, respectively, are shown in Figure 9. These results demonstrate that purified  $\Delta$ SCPA49 protein is an effective immunogen for the induction of specific systemic and secretory antibody responses in mice when administered intranasally.

#### **e) Impact of vaccine $\Delta$ SCPA49 on Clearance of Streptococci from Infected Mice.**

Experiments were performed to determine whether immunization with the C5a peptidase would enhance clearance of streptococci from the nasopharynx. Both hyperimmune rabbit and human sera that contain high levels of anti-SCPA antibody can neutralize SCPA activity *in vitro*. S.P. O'Connor et al., "The Human Antibody Response to Streptococcal C5a Peptidase," J. Infect. Dis., **163**, pp. 109-116 (1990). The fact that SCPA significantly facilitates colonization of the oral mucosa suggests that immunization of mice with purified  $\Delta$ SCPA49 could reduce the capacity of streptococci to colonize the nasopharynx. Mice were immunized intranasally with affinity purified, genetically inactivated SCPA to test this possibility. The truncated protein,  $\Delta$ SCPA49, was administered intranasally without adjuvants or carriers. Pharyngeal colonization of vaccinated mice by wild-type M<sup>+</sup> SCPA<sup>+</sup> streptococci differed significantly from those immunized with PBS in three independent experiments using mice vaccinated with two different preparations of purified  $\Delta$ SCPA49 protein (Tables 3 and 4; Figure 10). Only one of 13 mice immunized with  $\Delta$ SCPA49 protein was culture positive for streptococci ten days after inoculation (Table 4; Figure 10). In contrast, 30-58% of the non-vaccinated controls remained culture positive for six days, and some were still positive ten days after infection. The numbers of  $\beta$ -hemolytic, streptomycin resistant

colonies on blood agar plates also showed a significant difference between  $\Delta$ SCPA49 vaccinated and control mice. Different sets of immunized mice cleared serotype M49 streptococci significantly more rapidly from their nasopharynx than non-immunized control.

\* Mice were inoculated twice, because the dose of bacteria was too low at first time inoculation.

Last, it was examined whether SCP of one serotype would vaccinate animals against infection from other serotypes. There are more than 80 different serotypes of group A streptococci. An effective vaccine should prevent infection to more than one streptococcal serotype. Cross-protection was produced against colonization by the streptococcal OF<sup>+</sup> serotypes M2 and M11 and the OF<sup>-</sup> serotypes M1 and M6. The fact that rabbit serum directed against  $\Delta$ SCPA49 protein from serotype M49 streptococci neutralized peptidase activity associated with several serotypes suggested that intranasal immunization with a single subunit vaccine might reduce or eliminate pharyngeal colonization by those serotypes. To explore this possibility four groups of twenty mice were immunized by intranasal inoculation with affinity purified  $\Delta$ SCPA49 protein as described above. Control mice received PBS. Prior to being challenged with streptococci, serum and saliva samples from randomly chosen, immunized and control mice were assayed for anti-SCPA antibody. All immunized mice tested had developed a strong serum and measurable salivary antibody response. Pharyngeal colonization of mice immunized with  $\Delta$ SCPA49 protein by strains of all four serotypes was reduced relative to non-immunized controls. Differences were most significant on days 3 and 5 after inoculation (Table 5).

Table 5. Immune protectivity is serotype independent

	Day 3 after inoculation		Day 5 after inoculation	
	Nonimmune (+/total)	%	Immune (+/total)	%

		2		9
M6	14/20	70	12/19	63.
				2
				1

+ means culture positive mice. \* Differences between immunized and non-immunized mice are statistically significant ( $P < 0.05$ ). P values were calculated by  $\chi^2$  analysis.

Statistically significant differences were observed between immunized and control mice inoculated with serotype M2, M11 and M1 strains. However, the OF<sup>+</sup> serotypes M2 and M11 were more efficiently eliminated by immunized mice than were the OF<sup>-</sup> strains, M1 and M6. M1 streptococcal colonization of immunized mice was significantly reduced relative to control mice. Only 10.5% of the immunized mice were culture positive by day 5 post-infection. In contrast, 37% of the control mice were culture positive with this strain. Although immunized mice appeared to clear M6 streptococci more rapidly, the differences were not statistically significant. As in previous experiments the number of  $\beta$ -hemolytic streptococcal colonies on blood agar plates were significantly fewer in samples taken from vaccinated mice than those taken from control animals. Thus, the  $\Delta$ SCPA 49 protein was an effective vaccine that provided cross-protection against other streptococcal serotypes.

#### EXAMPLE 5

##### 15 Site-directed Mutagenesis of SCPA49

Group A streptococcal serotypes can be divided into two major groups, OF<sup>+</sup> and OF<sup>-</sup> strains. The latter are more often associated with rheumatic fever and toxic shock, whereas OF<sup>+</sup> strains are a common cause of impetigo and acute glomerulonephritis. Although the SCPA proteins of these groups are 95-98% identical, it is possible that the immune response to them may be somewhat different. This concern prompted efforts to develop defined variant SCPAs from an M1 OF<sup>-</sup> strain and from an M49 OF<sup>+</sup> strain in parallel. Amino acids that are required for catalytic activity were replaced with those expected to inactivate the enzyme (Figure 1). The N and C-terminal amino acid boundaries of SCPA49, expressed the pGEX-4T-1 subclones, were Asn<sup>32</sup> and His<sup>1139</sup>, respectively (Figures 1 and 8). Ser<sup>512</sup> (SCPA49S512A), Asn<sup>295</sup> (SCPA49N295A) and Asp<sup>130</sup> (SCPA49D130A) in the SCPA49 protein were replaced with Ala, and Asn<sup>295</sup> (SCPA49N295R) was replaced by Arg (Deborah Stafslie, M.S. Thesis, University of Minnesota).

20 The method used to introduce mutations into the *scpa49* gene from Streptococcus strain CS101 was the "megaprimer" method of site-directed mutagenesis. Barik, S., "Site directed mutagenesis in vitro megaprimer PCR,"

In: Methods in Molecular Biology, Vol. 57: In Vitro Mutagenesis Protocols, Humana Press, Inc. Totowa, NJ (1996). The serine mutation was introduced using primers *scpFor940* (5'-

CCCCCGGATCCAATACTGTGACAGAAGACACTCC-3'), SEQ ID NO:10,

- 5 and *scpmutrev1883* (5'- TTTCTGGAAGTAGTATGTCTGCGCC-3'), SEQ ID NO:11, to amplify a 1450 bp double-stranded PCR product. This first PCR product, a "megaprimer," was purified using the Qiagen Qiaquick Gel Extraction Kit, then used in a second asymmetrical PCR reaction to amplify the 3.3 kb *scpA49* gene containing the desired mutation. Five cycles of denaturation (93°C, 10 1 min) and extension (72°C, 5 min) were carried out before addition of the reverse primer *scpRev4263*, (3'-

CCCCCCTCGAGATGTAAACGATTTGTATCCTTGTCATTAG-3') SEQ ID NO:12. During the fifth cycle at 72°C, the reverse primer was added at a concentration of 1 mM. The amplification was completed using 25 cycles at

- 15 94°C for 1 min, 58°C for 2 min, and 72°C for 2-3.5 minutes. Reactant concentrations were the same as described in the previous section, except that a forward primer was not added and the megaprimer was added at a concentration of 4-6 µg per 100 µl reaction. This process yielded variant protein SCPA49S512A (see Table 6 below).

- 20 The aspartate and asparagine variants were constructed in much the same fashion, using the reverse primers *scpmutrev717* (5' -

CAGTGATTGATGCTGGTTTTGATAA- 3') SEQ ID NO:13 and

*scpmutrev1214* (5' - AGCTACTATCAGCACCAG - 3') SEQ ID NO:14 to

construct 311 bp and 805 bp megaprimers, respectively. The primer

- 25 *scpmutrev717* was used to generate variant protein SCPA49D130A, and primer *scpmutrev1214* was used to generate variant protein SCPA49N295A (see Table 6 below). After Qiaquick purification, however, the megaprimer was treated with 0.1 U mung bean nuclease (per 4 µg DNA) and incubated at 30°C for 10 minutes. The nuclease was removed by phenol/chloroform extraction, and the 30 megaprimer recovered in the aqueous phase by ethanol precipitation. The pellet was resuspended in 80 µl sterile double distilled water, and 37 µl of this was used in each 100 µl asymmetrical PCR reaction. The mutated gene was then

cloned into pGEX 4T-1 as previously described. Sequencing of variants was performed using <sup>35</sup>S-labeled dATP and the Sequenase kit (Stratagene) or using automated fluorescent sequencing at the University of Minnesota Microchemical Facility.

5 **Table 6: Amino acid sequence comparison of variant proteins**

The *E. coli* expression vector pGEX 4T-1 was used to overexpress variant SCPA as GST fusion proteins. Recombinant SCPA was purified according to the protocol provided in the GST Gene Fusion System Handbook (Pharmacia) previous to this work. The SCPA protein antigen was purified by affinity chromatography as described above.

#### EXAMPLE 6

##### Construction of SCPA1 and SCPB Variants

The wild-type *scpA1* gene was amplified by PCR from M1 serotype of *S. pyogenes* (strain 90-226) in the following manner. Primers were designed such that only a fragment of the complete gene would be expressed. This fragment corresponds to the start of the mature protein and terminates just before the cell wall associated domain residue Asn<sup>32</sup> through Asp<sup>1038</sup> (Figure 2). The forward primer 5' - CCCCCGAATTCATTACTGTG ACAGAAGACACTCCTGC - 3' (SEQ ID NO:15) anneals starting at base number 940 (numbering corresponding to that of Chen, C., and Cleary, P., "Complete nucleotide sequence of the streptococcal C5a peptidase gene of *Streptococcus pyogenes*," *J. Biol. Chem.*, 265:3161-3167 (1990). The opposing, reverse PCR primer, 5' - CCCCCGGATCCTTATTGTTCTGGTTATTAGA GTGGCC - 3' (SEQ ID NO:16) anneals at base number 3954 just upstream of a region of DNA repeats. This repeat region of the protein is predicted to be the part that passes through, and then attaches to the peptidoglycan of the cell wall. The italicized region of each primer is additional sequence that has been added to the *S. pyogenes* sequence to enable the cloning process. The underlined region of the forward

primer incorporates a *Eco*RI restriction site, the underlined portion of the reverse primer a *Bam*HI site. The reverse primer also incorporates a stop codon (TAA) in frame of the gene that terminates translation.

- The resultant PCR product corresponding to bases 940-3954 was cloned
- 5 into an intermediate vector pCR2.1 (Invitrogen, Inc.) and transformed into *E. coli* Top10F cells (Invitrogen, Inc.). Plasmid DNA from an appropriate transformant was restricted with *Eco*RI and *Bam*HI. The 3018 base fragment, containing the fragment of *scpA1*, was gel purified following standard procedures and ligated into the expression vector pTrc99a (Pharmacia) restricted
  - 10 with the same enzymes. This ligation was transformed into *E. coli* DH5 $\alpha$  cells and a transformant was selected that contained the desired plasmid construction. The resultant plasmid places the PCR fragment of *scpA1* behind a Shine-Dalgarno sequence and ATG start site, and is under the transcriptional control of the *trc* Promoter, that is inducible with the allolactose analogue IPTG.
  - 15 Site-specific genetic variants of the wild-type *scpA1* were constructed following a procedure described by C. L. Fisher and G. K. Pei, "Modification of a PCR-based site-directed mutagenesis method," BioTechniques, 23:570-574 (1997). The appropriate amino acid residues within SCPA1 important for protease activity were predicted by sequence comparisons to the family of
  - 20 subtilisin-like serine proteases. Siezen, R. J., et al., "Homology modeling and protein engineering strategy of subtilases, the family of subtilisin-like serine proteinases," Protein Engineering, 4:719-737 (1991); Chen, C., and Cleary, P., "Complete nucleotide sequence of the streptococcal C5a peptidase gene of *Streptococcus pyogenes*," J. Biol. Chem., 265:3161-3167 (1990). Three
  - 25 residues, conserved amongst this family, are involved in the formation of the active site. In SCPA1, these correspond to the Asp<sup>130</sup>, His<sup>193</sup>, and Ser<sup>512</sup>. Three sets of non-overlapping oligonucleotides were designed for use in PCR to alter each one of these amino acid residues. These oligonucleotides were designed to amplify away from each other on opposite strands of DNA. In each set, the 5'
  - 30 end of one of the primers would contain the codon encoding one of these amino acids for mutation and this codon would be altered to encode an alanine. These three sets of primers are listed below; the codons that are changes are italicized.

**D130A:**

Forward (SEQ ID NO:17)

5' - ATT *GCT* GCT GGT TTT GAT AAA AAT CAT GAA GCG - 3'

GAT codon change to GCT corresponds to an aspartate to alanine amino acid change.

Reverse (SEQ ID NO:18)

5' - CAC TGC AAC AAC AGT CCC - 3'

**H193A:**

Forward (SEQ ID NO:19)

10 5' - GAG *GCC* GGC ACA CAC GTG - 3'

CAC codon change to GCC corresponds to a histidine to alanine amino acid change.

Reverse (SEQ ID NO:20)

5' - TTG ATC GAC AGC GGT TTT ACC - 3'

15 **S512A:**

Forward (SEQ ID NO:21)

5' - ACT *GCT* ATG TCT GCT CCA TTA G -3'

ACT codon change to GCT corresponds to a serine to alanine amino acid change.

20 Reverse (SEQ ID NO:22)

5' - TCC AGA AAG TTT GGC ATA CTT GTT GTT AGC C

- These sets of PCR primers were used in three separate reactions. The template DNA was pLP605, which contained the wild-type *scpA1* sequence.
- 25 The PCR products were subsequently self-ligated and transformed into the *E. coli* strain Top10F' (Invitrogen, Inc.). Transformants were screened for the appropriate size and restriction pattern. The sequence change in the S512A variant destroys a unique *SpeI* restriction site so that this mutation could be identified directly by restriction analysis. All potential variants were confirmed
- 30 by DNA sequencing. Subsequently, the D130A mutation was combined with the S512A mutation to form a double variant utilizing a unique *PstI* site between these two regions of the protein. The final alteration was to change the antibiotic

selection from ampicillin to kanamycin by moving the variant *scpA1* genes to a previously altered pTRC99a vector (Pharmacia, Inc.) containing the kanamycin gene.

- A variant of SCPB protein was constructed using the method described above for SCPA1 mutants. The wild-type SCPB gene was cloned from group B streptococcus 78-471 (Type IIa<sup>+</sup>).

### EXAMPLE 7

#### Analysis of Variant Proteins

- Proteins expressed from each of the variant constructs were analyzed by SDS polyacrylamide gel electrophoresis. The expected size of the protein is 121 kD, however, the proline-rich cell wall spanning domain at the carboxy terminus of the enzyme causes the protein to run slightly slower during SDS-PAGE. Therefore the apparent molecular weight is 130 kD when determined by SDS-PAGE. Since active SCP could be harmful to the host, it was important that the variant proteins lacked enzymatic activity. Two properties of the variant proteins were evaluated. The specific activities of the wild-type and variant proteins as determined by PMN adherence assay are compared in Table 7. These experiments indicated that the substituted amino acids reduced enzymatic activity by greater than 90%.

**Table 7: PMN adherence assay determination of variant protease activity**

	Protein	Activity (U/mg*10 <sup>-3</sup> )
	Wild-type	170
	SCPA49D130A	<20
	SCPA49N295A	<20
25	SCPA49S512A	<20

- The variant proteins were also compared to the wild-type protein for their capacity to bind antibody directed against the wild-type enzyme. Competitive ELISA assays were used for this purpose. Competitive ELISAs measured the inhibition of antibody binding to immobilized antigen by soluble antigen. A constant amount of wild-type antigen was bound to wells of the microtiter plate. A constant amount of antibody is added at the same time with varying amounts of soluble competitive antigen. The slope of the percent inhibition versus

antigen concentration curves estimate the relative binding affinity of the soluble antigen for antibody. While the binding constants cannot be calculated without knowing the exact concentration of anti-SCPA in the antiserum, the relative binding affinities of several proteins were compared (Figure 11). Since the slopes of the percent inhibition versus concentration curves are the same for the wild-type and variant proteins, it was concluded that amino acid substitution did not alter the ability of antibody to bind to the variant proteins.

Recombinant SCPA1, SCPA49 and SCPB proteins were also determined to bind equally well to anti-SCP antibody (Figure 12). In this experiment the plate antigen was SCPA49 and the antibody was rabbit anti-SCPA49. The relative affinities of this antibody for these antigens, indicated by the slope of the curves is highly similar. These results demonstrate that SCPA protein from M49 OF<sup>+</sup> and M1 OF<sup>-</sup> group A Streptococci, and from group B streptococci are equivalent with regard to antibody recognition and may be used interchangeably in a vaccine preparation.

### EXAMPLE 8

#### Subcutaneous (SQ) Administration of SCPA Antigen Induces Protection in Mice

All earlier protection studies were performed by administering affinity purified SCPA49 protein intranasally without adjuvant. Intramuscular or SQ injection of antigens is historically a preferred, more accepted method of vaccine delivery. Therefore, experiments were performed to test whether SQ injections of SCPA with MPL/alum induced a protective immune response and whether that response reduced colonization when the challenge strain of group A streptococcus differed in serotype from the source of the SCPA vaccine. The capacity of immunized mice to clear streptococci from the oral-nasal pharyngeal mucosa was evaluated by throat culture or by sampling dissected nasal tissue. Representative throat culture data are presented in Table 8.

**Table 8: Subcutaneous vaccination of mice**

	Vaccine <sup>a</sup>	Challenge Bacteria <sup>b</sup>	Percent Colonized <sup>c</sup>	
			Control Mice	SCPA-Immunized Mice
5	SCPA49S512A	OF <sup>+</sup> M49	64% (3)	36%
	ΔSCPA49	OF <sup>+</sup> M49	64% (3)	20%
	ΔSCPA49	OF M1	33% (5)	8%
	SCPA1S512A	OF M49	23% (5)	8%

- 10 <sup>a</sup> Vaccines contained 10 µg of the indicated antigens mixed with adjuvants MPL and alum. Experimental groups each contained 13-20 mice. Control mice were immunized with tetanus toxoid mixed with the same adjuvant.
- <sup>b</sup> Mice were infected by intranasal inoculation.
- <sup>c</sup> Colonization was assessed by throat culture. The numbers in parentheses indicate the day on which the cultures were taken.
- 15

Mice immunized by SQ injection of each of the three different forms of SCPA antigen induced moderate protection. Immunization with ΔSCPA49 protected against both OF<sup>+</sup> M1 and OF<sup>+</sup> M49 strains. SCPA49S512A and

- 20 SCPA1S512A were chosen for subsequent study.

Persistence of streptococci following intranasal challenge was also assessed by a more quantitative assay. This method involved sacrificing groups of mice at different times following infection, and dissecting nasal tissue (NT), which was then assayed for viable streptococci (CFU). Standard amounts of NT

25 were homogenized in buffer and the number of CFU/mg tissue was determined by viable count.

Three groups of mice were immunized SQ with SCPA49S512A, SCPA1S512A or tetanus toxoid. All vaccines were mixed with MPL/Alum adjuvants as before. Mice received four injections of 5 µg protein antigen and

30 then challenged two weeks after the last injection. Nasal tissue was harvested 16 hours after challenge with the OF<sup>+</sup> M49 strain CS101. The geometric means of CFU/mg tissue are shown in Table 9.

**Table 9: Geometric means of CFU/mg nasal tissue**

Vaccine Antigen	16 hours <sup>a</sup>
Tetanus	5.71 <sup>b</sup>
SCPA49S512A	2.27
SCPA1S512A	1.60

<sup>a</sup> The time at which NT was taken following intranasal infection of mice.

<sup>b</sup> Values are log values.

- 10 The number of streptococci associated with nasal tissue decreased with time, as expected and the decrease was more rapid and complete in mice immunized with SCPA antigen. All groups of mice that had been immunized with SCPA retained fewer streptococci than control mice. In this experiment immunization with SCPA1S512A was most effective and induced a cross-
- 15 protective response, since the challenge strain CS101 is OF<sup>+</sup> M49 and the source of vaccine protein SCPA1S512A from an OF<sup>-</sup> M1 strain. These results confirm that a single SCPA antigen can induce protection against heterologous serotypes. Protection is afforded by antibody that neutralizes peptidase activity on the bacterial surface. This increases the influx of phagocytes within a few hours
- 20 from the time streptococci are deposited on mucosal tissue. Rapid clearance of streptococci by phagocytes is presumed to prevent subsequent multiplication and persistence of the bacteria. Mice uniformly had serum IgG titers of 1:32,000 or greater when assayed by ELISA, indicating that SQ injection of SCPA antigen with adjuvant consistently induced a vigorous antibody response.

25

#### EXAMPLE 9

##### **C5a Peptidase from Group B Streptococci Is Nearly Identical in Sequence to Those from M12 and M49 Group A Streptococci**

- The group B streptococci C5a peptidase (SCPB) gene was cloned, sequenced and compared to that from serotype group A streptococci M12 and
- 30 M49. The entire *scpB* gene was amplified by PCR using primers which correspond to portions of the *scpA12* sequence using the method described above. The SCPB gene encodes an open reading frame (ORF) of 3450 bp which specifies a protein of 1150 amino acids with Mr of 126,237 da. The amino acid sequence of SCPB is shown in Figure 2. Comparison of the *scpB* nucleotide and

deduced amino acid sequence to those from M12 and M49 group A streptococci showed high similarities, 98% and 97%, respectively. *ScpB* contained a 50 bp deletion which overlapped two of the C-terminal repeats, and had several other minor differences relative to *scpA* genes. Alignment of the sequences showed  
5 that *scpA12* is actually phylogenetically closer to *scpB* than it is to *scpA49*. Thirty strains, representing serotypes III, III/R, II, Ia/c, NT/c, NT/c/R1 carry a copy of *scpB*.

Recombinant SCP was expressed in *E. coli* using expression vector plasmid pGEX-4T-1 (ATCC accession number 98225) and was shown to be  
10 identical to the enzyme extracted from the parental group B streptococcal strain 78-471 (Type II a+ b). Western blot analysis suggested the recombinant SCP is identical to the C5ase enzyme previously purified from group B streptococci.
